Thermal Fault Diagnostics in Lithium-ion Batteries
based on a Distributed Parameter Thermal Model

Satadru Dey, Hector E. Perez and Scott J. Moura

Abstract—Lithium-ion (Li-ion) battery faults are potentially hazardous to battery health, safety and performance. Thermal fault mechanisms represent a critical subset of such failures. To ensure safety and reliability, battery management systems must have the capability of diagnosing these thermal failures. We present a Partial Differential Equation (PDE) model-based scheme for diagnosing thermal faults in Li-ion batteries. For this study, we adopt a distributed parameter one-dimensional thermal model for cylindrical battery cells. The diagnostic scheme objective is to detect and estimate the size of the thermal fault. The scheme consists of two PDE observers arranged in cascade. The first observer, denoted as Robust Observer, estimates the distributed temperature inside the cell under nominal (healthy) and faulty conditions. The second observer, denoted as Diagnostic Observer, receives this estimated temperature distribution, and in turn outputs a residual signal that provides the fault information. Lyapunov stability theory has been utilized to verify the analytical convergence of the observers under healthy and faulty conditions. Simulation studies are presented to illustrate the effectiveness of the scheme.

I. INTRODUCTION

Thermal failure and degradation mechanisms constitute an important subset of battery faults that can potentially deteriorate battery performance and safety [1]. Some of these thermal failures, e.g. thermal runaway, may even lead to catastrophic events if not detected or diagnosed early enough. Therefore, diagnosis of battery thermal failures is extremely important to ensure safe and reliable operation. In this paper, we propose a Partial Differential Equation (PDE) model-based diagnosis scheme for thermal faults in Li-ion batteries.

In the battery controls/estimation literature, real-time estimation of State-of-Charge (SOC) and State-of-Health (SOH) have received substantial attention in the past decade [2] [3] [4] [5] [6] [7]. Compared to SOC and SOH estimation, temperature estimation problems have received significantly less attention. There are some recent studies. For example, algorithms for core temperature estimation [8] [9], and distributed temperature estimation [10] are proposed.

The body of literature on real-time fault diagnosis problems in batteries is significantly smaller than estimation problems. Some of the existing approaches deal with sensor and actuator faults [11] [12] [13], electrochemical faults [14], overcharge/over-discharge faults [15], and terminal voltage collapse [16]. However, real-time diagnosis of thermal faults is almost unexplored in the existing published literature, despite its critical importance for battery safety and performance. A few efforts exist in battery thermal fault diagnostics that utilize average thermal model [11] and two-state thermal model [17] to diagnose certain thermal faults. These approaches, however, (i) rely on lumped parameter thermal models which may not be sufficient to capture the effect of distributed thermal faults inside the cell, and (ii) do not estimate fault size. Note that information on fault size can be crucial for thermal management under faulty conditions.

In the present paper, we extend this research by proposing a battery thermal fault diagnosis scheme which (i) utilizes a distributed parameter thermal model and, (ii) detects and estimates the thermal fault size.

In the proposed diagnostic scheme, we adopt an onedimensional distributed parameter thermal model of a cylindrical battery cell [18]. The scheme consists of two PDE observers arranged in cascade and utilizes measured surface temperature feedback. The first observer, denoted as Robust Observer, estimates the distributed temperature inside the cell under healthy and faulty conditions. Robust state estimation is a bi-product of this scheme that provides convergent estimate of the temperature distribution inside the battery cell irrespective of healthy or faulty conditions. The second observer, denoted as Diagnostic Observer, receives this estimated temperature distribution information from Robust Observer and in turn outputs a residual signal that provides the fault information. The backstepping transformation and Lyapunov stability theory [19] have been utilized to design and analyze the observer. Furthermore, the residual signals are compared with non-zero thresholds to incorporate robustness to modeling and measurement uncertainties. These non-zero thresholds are designed offline based on the probability distribution of the residual signals under fault-free conditions.

The rest of the paper is organized as follows. Section II introduces the distributed parameter thermal model of the battery cell. Section III designs and analyzes the fault diagnosis scheme in detail. Simulation studies are presented in Section IV. Finally, Section V concludes the work.

Notations: In this paper, following notations are used: \[ \|u(t)\| = \sqrt{\int_0^1 u^2(x)dx}, \quad u_x = \frac{\partial u}{\partial x}, \quad u_{xx} = \frac{\partial^2 u}{\partial x^2}. \]

II. DISTRIBUTED PARAMETER THERMAL MODEL FOR LI-ION BATTERIES

Nominal Model: We adopt the following (nominal or fault-free) one-dimensional thermal model that predicts the radially distributed temperature dynamics of a cylindrical battery

\[ u_t = \frac{\partial^2 u}{\partial x^2}, \]
\[ \beta \frac{\partial \bar{T}}{\partial t}(r,t) = \frac{1}{r} \frac{\partial \bar{T}}{\partial r}(r,t) + \frac{\dot{Q}(t)}{k} \]  
with Neumann boundary conditions

\[ \frac{\partial \bar{T}}{\partial r}(0,t) = 0, \quad \frac{\partial \bar{T}}{\partial r}(R,t) = \frac{h}{k} (T_{\infty} - \bar{T}(R,t)) , \]  
where \( t \in \mathbb{R}^+ \) represents time and \( r \in [0, R] \) is the spatial coordinate in the radial direction. The parameter \( k \) is the thermal conductivity of the battery cell, \( \dot{Q}(t) \) is the volumetric heat generation rate, \( h \) is the convection coefficient and \( \beta = (\rho C_p) / k \) is the inverse of thermal diffusivity, where \( \rho \) is the mass density and \( C_p \) is the specific heat capacity.

Next, we: (i) perform a state transformation yielding a simpler PDE in new space variable \( \bar{x} \) and time \( \bar{t} \) and, ii) then scale the space and time variables in the new PDE by defining \( T(x,t) = \bar{T}(\bar{x},\bar{t}) \) with \( x = \bar{x}/R \), \( t = \bar{t}/\beta R^2 \) and \( k = k/R^2 \). This transformation and scaling results in the following system:

\[ T_x(t,x) = T_{xx}(x,t) + \frac{\dot{Q}(t)}{k} , \]  
with Neumann boundary conditions

\[ T_x(0,t) = 0, \quad T_x(1,t) = \frac{h}{k} (T_{\infty} - T(1,t)) \],

where \( t \in \mathbb{R}^+ \) and \( x \in [0, 1] \). The remainder of this paper considers (3)-(4) as the plant model.

Furthermore, we adopt a second order electric circuit model to capture the electrical dynamics of the battery (see Fig. 1) [20]. The electrical circuit consists of an open circuit voltage source \( (V_{oc}) \), an internal series resistance \( (R_{int}) \) and two resistance-capacitance branches in series. Furthermore, it is assumed that the SOC of the battery is computed online via Coulomb-counting. The state-space equations for the electrical model are:

\[ \frac{dSOC}{dt}(t) = - \frac{I(t)}{C_{batt}} , \]  
\[ \frac{dV_1}{dt}(t) = - \frac{V_1(t)}{R_1 C_1} + \frac{I(t)}{C_1} , \]  
\[ \frac{dV_2}{dt}(t) = - \frac{V_2(t)}{R_2 C_2} + \frac{I(t)}{C_2} , \]  
\[ V_{term}(t) = V_{oc}(SOC) - V_1(t) - V_2(t) - R_{int} I(t) , \]

where \( I(t) \) is the battery current, \( C_{batt} \) is the battery charge capacity in Amp-sec and \( V_{term} \) is the terminal voltage. The open circuit voltage \( (V_{oc}) \) is a function of the State-of-Charge (SOC) and computed online. This function can be determined via offline experimental studies. In this distributed parameter model, \( R_{int} \) is assumed to have Arrhenius dependence on the average battery temperature \( T_{avg} \) given as: \( R_{int} = f(T_{avg}) \) where \( f(T_{avg}) = R_{int,ref} \cdot \exp \left( \frac{T_{avg} - T_{ref}}{T_{ref}} \right) \) and \( R_{int,ref} \) is a known reference value at a known reference temperature \( T_{ref} \). The average temperature of the cell is given by \( T_{avg}(t) = \int_0^1 T(x,t) \, dx \).

**Fig. 1. Battery electrical circuit model**

**Measurements:** Measured variables include the current \( (I) \), terminal voltage \( (V_{term}) \), and surface temperature \( (T(1)) \).

**Remark 1.** The heat generation rate \( \dot{Q} \) is expressed as:

\[ \dot{Q}(t) = \frac{1}{v_b} I(t)(V_{oc}(SOC) - V_{term}(t)) . \]

where \( v_b \) is the battery cell volume. In this work we assume that \( \dot{Q} \) is computed online using the measured variables \( V_{term}, I, \) and \( V_{oc}(SOC) \), which is computed using the SOC information from (5). Furthermore, we assume that the electrical states \( V_1 \) and \( V_2 \) are computed online via the open-loop model (6)-(7).

**Fault Model:** The faulty battery thermal dynamics can be mathematically modeled as

\[ T_x(t,x) = T_{xx}(x,t) + \frac{\dot{Q}(t)}{k} + \Delta Q(x,t) , \]

with Neumann boundary conditions

\[ T_x(0,t) = 0, \quad T_x(1,t) = \frac{h}{k} (T_{\infty} - T(1,t)) \],

where \( \Delta Q(x,t) \) represents a distributed thermal fault, such as abnormal heat generation from electrochemical side reactions, or failure due to mechanical or thermal abuse [1][21].

**III. FAULT DIAGNOSIS SCHEME**

The fault diagnosis scheme is diagramed in Fig. 2. The scheme consists of two observers working in cascade. The first observer, **Robust Observer**, uses the surface temperature feedback and estimates the distributed battery cell temperature under healthy and faulty condition. The second observer, **Diagnostic Observer**, receives the estimated temperature distribution from **Robust Observer** and in turn provides a residual signal. The residual signal is used for detection and estimation of the thermal fault \( (\Delta Q) \). In the next subsections, we will discuss the design of these two observers.

**A. Robust Observer**

The following structure is chosen for the **Robust Observer**,\n
\[ \dot{T}_{1x}(t,x) = \dot{T}_{1xx}(x,t) + \frac{\dot{Q}(t)}{k} + P_1(x)\dot{T}_1(1,t) , \]

with Neumann boundary conditions

\[ \dot{T}_{1x}(0,t) = 0, \quad \dot{T}_{1x}(1,t) = \frac{h}{k} (T_{\infty} - T(1,t)) + P_{10}\dot{T}_1(1,t) , \]

\[ \dot{\hat{T}}_1(t,x) = \frac{1}{\rho C_p} \nabla \cdot [k \nabla \hat{T}_1(t,x)] + \frac{\dot{Q}(t)}{k} + P_1(x)\hat{T}_1(1,t) , \]

where \( k \) is the thermal conductivity of the battery cell, \( \dot{Q}(t) \) is the volumetric heat generation rate, \( h \) is the convection coefficient and \( \beta = (\rho C_p) / k \) is the inverse of thermal diffusivity, and \( \rho \) is the mass density and \( C_p \) is the specific heat capacity.
where $\bar{T}_1(x,t)$ is the estimated temperature distribution, $\bar{T}_1(1,t) = T(1,t) - \hat{T}_1(1,t)$ is the boundary estimation error and $P_1(x)$ and $P_{10}$ are the observer gains to be determined.

The error dynamics of the Robust Observer are given by subtracting (12)-(13) from (10)-(11),
\begin{equation}
\dot{T}_1(x,t) = \Delta Q(x,t) - P_1(x)\bar{T}_1(1,t), \quad (14)
\end{equation}
\begin{equation}
\dot{T}_1(0,t) = 0, \quad \dot{T}_1(1,t) = -P_{10}\bar{T}_1(1,t). \quad (15)
\end{equation}

Next, we follow the backstepping approach to analyze the error dynamics and design the observer gains [19]. The backstepping approach seeks the linear Volterra transformation $\hat{T}_1(x,t) = \omega(x,t)$
\begin{equation}
\hat{T}_1(x,t) = \omega(x,t) - \int_0^1 P(x,y)\omega(y,t)dy, \quad (16)
\end{equation}
which transforms (14)-(15) to the following target error system
\begin{equation}
\omega_t(x,t) = \omega_{xx}(x,t) + \Delta \omega_Q(x,t) - c\omega(x,t), \quad (17)
\end{equation}
\begin{equation}
\omega_x(0,t) = 0, \quad \omega_x(1,t) = 0, \quad (18)
\end{equation}
with $c > 0$ as a parameter of user’s choice and $\Delta \omega_Q(x,t) = \Delta \omega_{Q}(x,t) - \int_0^1 P(x,y)\Delta \omega_Q(y,t)dy$. Note that, the gain kernel $P(x,y)$ in (16) must satisfy the following conditions:
\begin{equation}
P_{yy}(x,y) - P_{xx}(x,y) = cP(x,y), \quad (19)
\end{equation}
\begin{equation}
P(x,x) = -c\frac{x^2}{2}, \quad P_x(0,y) = 0, \quad (20)
\end{equation}
and the observer gains can be computed as:
\begin{equation}
P_1(x) = -P_y(x,1), \quad P_{10} = -P(1,1). \quad (21)
\end{equation}

Remark 2. There exists a unique and closed-form solution of the kernel PDE (19)-(20) [19], given by
\begin{equation}
P(x,y) = -cy\frac{I_1(\sqrt{c(y^2-x^2)})}{\sqrt{c(y^2-x^2)}}. \quad (22)
\end{equation}

Therefore, the observer gains can be computed offline via (21) using the closed form solution (22).

Remark 3. It can be proven that the transformation (16) is linear and invertible [19]. Hence, stability of the target system (17)-(18) implies stability of the original system (14)-(15). Next, we present a theorem for the convergence of the Robust Observer via stability analysis of the target system.

**Theorem 1 (Performance of Robust Observer).** Consider the error dynamics (17)-(18). If $c > 0$, then
(a) under Scenario 1: $\Delta \omega_Q = 0$ i.e. in the presence of no fault, the origin of the error dynamics $\omega(x,t) = 0$ is exponentially stable in the sense of the spatial $H_1$ norm.
(b) under Scenario 2: $\Delta \omega_Q \neq 0$ i.e. in the presence of a fault, the error $\omega(x,t)$ remains bounded in the sense of spatial $H_1$ norm, i.e. $||\omega||_{H_1} \leq R_B \triangleq \sqrt{2c ||\Delta \omega_Q||^2}$ as $t \to \infty$.

**Proof.** We consider the square of the spatial $H_1$ norm as a Lyapunov function candidate to analyze the error dynamics (17)-(18):
\begin{equation}
W_1(t) = \frac{||\omega||^2 + ||\omega_x||^2}{2} \quad (23)
\end{equation}
\begin{equation}
\triangleq \frac{1}{2} \int_0^1 \omega'(x,t)dx + \frac{1}{2} \int_0^1 \omega^2(x,t)dx. \quad (24)
\end{equation}

The derivative of $W_1(t)$ along the state trajectory can be written as:
\begin{equation}
\dot{W}_1(t) = \int_0^1 \omega_t dx + \int_0^1 \omega_x \omega_{xt} dx. \quad (25)
\end{equation}

Now consider the first term of the right hand side of (25),
\begin{equation}
\int_0^1 \omega_t dx = \int_0^1 \omega_{x} dx + \int_0^1 \omega_{xx} dx - c \int_0^1 \omega^2 dx. \quad (26)
\end{equation}

Applying integration by parts on the first term and the Cauchy-Schwarz inequality on the second term of the right hand side of (26) yields
\begin{equation}
\int_0^1 \omega_t dx \leq - ||\omega_x||^2 + ||\omega|| \||\Delta \omega_Q|| - c ||\omega||^2 \quad (27)
\end{equation}

Now applying integration by parts on the second term of right hand side of (25), we have
\begin{equation}
\int_0^1 \omega_x \omega_{xt} dx = - \int_0^1 \omega_{xx} dx \quad (28)
\end{equation}

Next applying integration by parts on the second and third terms of the right hand side of (28), we have
\begin{equation}
\int_0^1 \omega_x \omega_{xt} dx = - \int_0^1 \omega_{xx} dx + \int_0^1 \omega_x \Delta \omega_Q dx - c \int_0^1 \omega_{xx} dx. \quad (29)
\end{equation}

Further, we apply Cauchy-Schwarz inequality on the second term of right hand side of (29) which yields
\begin{equation}
\int_0^1 \omega_x \omega_{xt} dx \leq - ||\omega_{xx}||^2 + ||\Delta \omega_Q|| ||\omega_x|| - c ||\omega_x||^2. \quad (30)
\end{equation}

Finally, considering (27) and (30) we can write the upper bound of the derivative of the Lyapunov function
\begin{equation}
\dot{W}_1(t) \leq ||\omega|| \|(\|\Delta \omega_Q\| - c ||\omega||) + ||\omega_x|| \|(\|\Delta \omega_Q\| - c ||\omega_x||)\|. \quad (31)
\end{equation}
Now considering Scenario 1: $\Delta \omega_Q = 0$, we can write (31) as
$$
\dot{W}_1(t) \leq -2cW_1(t). \tag{32}
$$
If $c > 0$ the comparison principle applied to (32) gives $W_1(t) \leq W_1(0) \exp(-2ct)$, which confirms the exponential convergence of $W_1(t)$. Hence, the origin of the error dynamics $\omega(x, t) = 0$ is exponentially stable in the sense of the spatial $H_1$ norm.

Next, we consider Scenario 2: $\Delta \omega_Q \neq 0$. From (31), the sufficient conditions for the negative definiteness of $\dot{W}_1(t)$ are
$$
\|\omega\| > \frac{\|\Delta \omega_Q\|}{c}, \|\omega_x\| > \frac{\|\Delta \omega Q_x\|}{c}. \tag{33}
$$
Squaring both sides of the conditions in (33) and adding them, we can write a single sufficiency condition as the square of $H_1$ norm:
$$
\frac{\|\omega\|^2 + \|\omega_x\|^2}{2} > R_B^2 \triangleq \frac{\|\Delta \omega_Q\|^2 + \|\Delta \omega Q_x\|^2}{2c^2}. \tag{34}
$$
Therefore, we can conclude that the negative definiteness of $\dot{W}_1(t)$ will hold outside the ball of radius in the $\|\omega\|_{H_1}$ space defined by $R_B$. Hence, $W_1(t)$ will settle on or within a bounded ball of radius $R_B$. This implies $\|\omega\|_{H_1} \leq R_B$ as $t \to \infty$. The magnitude of $R_B$ can be made arbitrarily small by choosing a high value of $c$.

**B. Diagnostic Observer**

The Diagnostic Observer utilizes the estimated temperature distribution from Robust Observer as a feedback signal.

**Remark 4.** The estimated temperature from Robust Observer can be written as: $\tilde{T}_1(x, t) = T(x, t) + \epsilon(x, t)$. However, we have proven that $\epsilon$ can be made arbitrarily small by selecting $c$ arbitrarily large. Hence, we consider $\tilde{T}_1(x, t) \approx T(x, t)$ for all practical purposes in the following analysis.

**Assumption 1.** We assume the following structure of the fault function $\Delta_Q(x, t) = \theta \psi(T(x, t), I(t))$, where $\psi(\cdot, \cdot)$ is a known function of distributed state $T(x, t)$ and input current $I$, and $\theta \in \mathbb{R}$ is an unknown constant parameter which determines the fault size. The main objective of the diagnostic observer is to estimate the value of $\theta$.

Considering Remark 4 and Assumption 1, the following structure is chosen for the Diagnostic Observer,
$$
\dot{T}_2(x, t) = \tilde{T}_{2xx}(x, t) + \hat{Q}(t) + \hat{\theta} \psi(T(x, t), I(t)) + L_2 \tilde{T}_2(x, t), \tag{35}
$$
with Neumann boundary conditions
$$
\tilde{T}_2(0, t) = 0, \tilde{T}_2(1, t) = \frac{h}{k} (T_\infty - T(1, t)), \tag{36}
$$
where $\tilde{T}_2(x, t)$ is the estimated temperature distribution by Diagnostic Observer, $\tilde{T}_2(x, t) = T(x, t) - \tilde{T}_2(x, t)$ is the distributed estimation error with $T(x, t)$ as the estimated temperature distribution from Robust Observer, $\hat{\theta}$ is the estimated size of the fault and, $L_2 \in \mathbb{R}$ is an observer gain to be determined. The update law for $\hat{\theta}$ is chosen as
$$
\dot{\hat{\theta}} = \frac{1}{L_3} \int_0^1 \psi(T(x, t), I(t)) \tilde{T}_2(x, t) dx, \tag{37}
$$
where $L_3 > 0$ is a user-defined gain that determines the parameter convergence rate. Subtracting (35)-(36) from (10)-(11), we can write the error dynamics of Diagnostic Observer as
$$
\dot{\tilde{T}}_2(x, t) = \tilde{T}_{2xx}(x, t) + \hat{\theta} \psi(T(x, t), I(t)) - L_2 \tilde{T}_2(x, t), \tag{38}
$$
with Neumann boundary conditions
$$
\tilde{T}_2(0, t) = \tilde{T}_2(1, t) = 0, \tag{39}
$$
In the following theorem, we analyze the performance of the Diagnostic Observer.

**Theorem 2** (Performance of Diagnostic Observer). Consider the error dynamics (38)-(39) and the parameter update law (37). If Remark 4 and Assumption 1 are valid and $L_2 \geq -\frac{1}{4}$, then the distributed state estimation error $\tilde{T}_2(x, t)$ and parameter estimation error $\hat{\theta}$ will be bounded. i.e. $\|\tilde{T}_2\|, \|\hat{\theta}\| \in \mathbb{L}_\infty$ as $t \to \infty$.

**Proof.** We consider the following Lyapunov function candidate to analyze the error dynamics
$$
W_2(t) = \frac{1}{2} \int_0^1 \tilde{T}_2^2(x, t) dx + \frac{L_3}{2} \hat{\theta}^2 \tag{40}
$$
Now considering (38) and the fact $\dot{\hat{\theta}} = 0$, the derivative of $W_2(t)$ along the state trajectories can be written as
$$
\dot{W}_2(t) = \int_0^1 \tilde{T}_2 \tilde{T}_{2xx} dx - L_2 \int_0^1 \tilde{T}_2^2 dx + \hat{\theta} \int_0^1 \psi(T, I) \tilde{T}_2 dx - L_2 \hat{\theta} \dot{\hat{\theta}} \tag{41}
$$
Next applying integration by parts on the first term of the right hand side of (41) and then applying Poincaré inequality: $\int_0^1 \tilde{T}_{2xx} dx \leq -\frac{1}{4} \int_0^1 \tilde{T}_2^2 dx$, we have
$$
W_2(t) \leq -\frac{1}{4} \int_0^1 \tilde{T}_2^2 dx - L_2 \int_0^1 \tilde{T}_2^2 dx + \hat{\theta} \int_0^1 \psi(T, I) \tilde{T}_2 dx - L_2 \hat{\theta} \dot{\hat{\theta}} \tag{42}
$$
Finally, applying the update law (37) on (42), we can write:
$$
\dot{W}_2(t) \leq -\frac{1}{4} (L_2 + L_3) \int_0^1 \tilde{T}_2^2 dx. \tag{43}
$$
From (43) it can be concluded that $W_2(t)$ is negative semidefinite if $L_2 \geq -\frac{1}{4}$. Hence, the estimation errors $\hat{\theta}$ and $\tilde{T}_2(x, t)$ will be bounded. i.e. $\|\tilde{T}_2\|, \|\hat{\theta}\| \in \mathbb{L}_\infty$ as $t \to \infty$.

**Remark 5.** The parameter estimate $\hat{\theta}$ will be used as a residual signal which serves the purpose of detection (indicated by
the fact $\hat{\theta} \neq 0$) and estimation (indicated by the magnitude of $\hat{\theta}$) of the thermal fault $\Delta Q$. The presence of modeling and measurement uncertainties prohibits the residual $\hat{\theta}$ from having the ideal property of equaling zero in the absence of a fault. We handle the effect of uncertainties by comparing the residual with a nonzero threshold. The residual will be evaluated as follows: A fault is detected when $\hat{\theta} > th$; no fault when $\hat{\theta} \leq th$, where $th$ is the predefined threshold.

**Remark 6.** The convergence properties of the Robust Observer and Diagnostic Observer are analyzed separately. This is enabled by the following facts: (i) The interaction between the two observers is one directional (from Robust Observer to Diagnostic Observer); (ii) The parameter $c$ can be chosen arbitrarily small to yield arbitrarily small $T_1$ and therefore error from Robust Observer can be neglected.

### IV. Simulation Studies

In this section, we conduct simulation studies to test the effectiveness of the scheme. The battery under consideration is a commercial Lithium Iron Phosphate A123 26650 cylindrical cell with rated capacity of 2.3 Ah. Battery parameters are taken from [10] [20]. In simulation, applied current to the battery and corresponding voltage and temperature responses under no fault condition are shown in Fig. 3 and Fig. 4. To emulate a realistic scenario, we inject following zero mean Gaussian noises in the measured quantities: 10mA current ($I$) noise, 0.3°C surface temperature ($T_s$) noise and 5mV voltage ($V_{term}$) noise. Under these assumed uncertainties, we select a a constant threshold value for the residual signal ($\hat{\theta}$) following the procedure discussed in the previous section. In the following results, the performance of the observers will be shown in terms of spatially averaged temperature, i.e. $T_{avg} = \int_0^1 T(x,t)dx$ and $T_{1-avg} = \int_0^1 T_1(x,t)dx$ where $T(x,t)$ represents actual temperature and $T_1(x,t)$ represent estimated temperatures with $i \in \{1,2\}$. Furthermore, we will quantify the convergence performance of the estimates in terms of convergence time defined as the time taken to reach within $\pm 2\%$ band of the true value starting from the incorrect initial condition. The observer estimates are provided in Fig. 5 under no fault condition. To verify the convergence properties, the observers are initialized with incorrect temperature 295 K, 3 K less than the true initial condition of 298 K. Recall from Theorem 1 that we have proven exponential stability of $T_1(x,t)$ to the origin, in the sense of spatial $H_2$ norm. Theorem 2 proves boundedness of the $L_2$ norm of $T_2(x,t)$, i.e. $\|T_2\| \in L_{\infty}$. In Fig. 5, both $T_{1-avg}$ and $T_{2-avg}$ from the Robust Observer and Diagnostic Observer, respectively, converge to the true temperature $T_{avg}$. The convergence time for both observers are within 0.1 sec. This is expected, of course, since the fault does not occur until 50sec. Furthermore, the estimated parameter $\hat{\theta}$ converges to a neighborhood of the true fault size $\theta$, as shown in the bottom subplot in Fig. 7. Recall that Theorem 2 only guarantees boundedness of $\hat{\theta}$, i.e. $|\hat{\theta}| \in L_{\infty}$. Nevertheless, we find the estimate can be successfully used to estimate fault size. In this case, the detection time is 1 sec whereas the fault estimate ($\hat{\theta}$) converges to the true value ($\theta$) within 5 sec.

### V. Conclusions

This paper presents a PDE-observer based scheme for diagnosing thermal faults in Li-ion batteries. We consider a distributed parameter thermal model coupled to a second order electrical model for diagnostic scheme design. The scheme consists of two PDE observers working in cascade. The first observer, Robust Observer, estimates the internal temperature distribution. The second observer, Diagnostic Observer, utilizes this estimated temperature distribution and in turn detects and estimates thermal faults. The proposed
scheme is tested on a case study of an internal heat generation fault. Simulation results illustrate the proposed scheme. Future work includes experimental validation.
